Abstract. The oceanic circulation over the southwestern Atlantic shelf is influenced by large tidal amplitudes, substantial freshwater discharges, high wind speeds and – most importantly – by its proximity to two of the largest western boundary currents of the world ocean: the Brazil and Malvinas currents. This review article aims to discriminate the dynamical processes controlling the interaction between this extensive shelf region and the deep-ocean. The discussion is focused on two broad regions: the South Brazil Bight to the north, and Patagonia to the south. The exchanges between the Brazil Current and the South Brazil Bight are characterized by the intermittent development of eddies and meanders of the Brazil Current at the shelfbreak. However, it is argued that this is not the only – nor the most important – influence of the Brazil Current on the shelf. Numerical simulations show that the thermohaline structure of the South Brazil Bight can be entirely ascribed to steady state, bottom boundary layer interactions between the shelf and the Brazil Current. The Malvinas Current does not show the development of eddies and meanders, but its influence on the Patagonian shelf is not less important. Models and observations indicate that the Malvinas Current not only controls the shelfbreak dynamics and cross-shelf exchanges but also influences the circulation in the shelf's interior.

1 Introduction

The southwestern Atlantic shelf extends from Cape Frio, Brazil ($\sim 23^\circ$ S) to Burdwood's Bank ($\sim 55^\circ$ S) (Fig. 1). Relatively narrow at its northern end, (~ 70 km near Cape Frio) it widens progressively to the south, reaching a maximum width of approximately 860 km near Rio Coig ($\sim 51^\circ$ S). The coastline geometry is dominated by the jagged indentations of several gulfs in the south, the wide chasm of the La Plata estuary in the center, and the crescent shape of the South Brazil Bight in the north. The shelf circulation consists of a northward flow of cold waters in the south and a southward flow of warm waters in the north (Piola et al., 2000; Palma et al., 2008) (Fig. 1). The deep circulation is characterized by the opposing flows, and confluence, of the Brazil and Malvinas currents (Gordon, 1989). The Malvinas Current (MC) is a swift, barotropic, and narrow branch of the Antarctic Circumpolar Current that flows north along the continental slope of Argentina up to approximately 38° S (Matano et al., 1993). Its volume transport ranges between 40 and 70 Sv (Peterson, 1992; Spadone and Provost, 2009). The Brazil Current (BC) is a highly baroclinic western boundary current that concentrates the bulk of its volume transport, between 25 and 40 Sv, in the top 500 m of the water column (Piola and Matano, 2001). The collision of these two currents, known as the Brazil/Malvinas Confluence, occurs near the mouth of the La Plata River where it creates a region of intense mesoscale variability.

The Sub-Tropical Shelf Front, which is located near 33° S, divides the southwestern Atlantic shelf in two distinct regions: a northern region with warm and salty waters of

tropical and subtropical origin, and a southern region with cold and relatively fresh waters of sub Antarctic origin (Piola et al., 2000). There have been exiguous attempts to understand the influence of the BC and MC on the southwestern Atlantic shelf. Campos et al. (1995, 2000) documented penetrations of meanders of the BC onto the South Brazil Bight, a phenomenon dynamically similar to that observed in the eastern coast of North America (e.g., Loder et al., 1998). Palma and Matano (2009) argued that bottom boundary layer processes largely control cross-shelf exchanges in this region. There are fewer studies on the exchanges between the MC and the Patagonian shelf. Saraceno et al. (2004) noted that, unlike the BC, the inshore boundary of the MC is remarkably stable. Malvinas waters, nevertheless, still percolate over the Patagonian shelf and influence the regional ecosystems (Piola et al., 2010). The most obvious evidence of this nutrient pumping is the high level of biological activity that is found in the Patagonia region, which is considered a Class I marine ecosystem with a productivity rate larger than $300 \text{ gr C/m}^2 \text{ yr}^{-1}$ (Csirke, 1997; Brandhorst and Castelo, 1971; Lutz and Carreto, 1991; Sabatini et al., 2004).

In fact, compared with Patagonia the Brazilian shelf is remarkably poor. The fish catch off southern Brazilian waters, for example, is an order of magnitude smaller than that over the Patagonia region (FAO, 2009; Haimovici et al., 2006). The interactions between the Patagonian shelf and the Southern Ocean are particularly relevant to our understanding of the global carbon budget since it is known that it absorbs large amounts of CO_2 from the atmosphere (Bianchi et al., 2005, 2009). The largest absorptions are associated with high chlorophyll regions, which are presumably maintained by vigorous vertical circulations near tidal fronts and along the shelfbreak. Most of the CO_2 is absorbed in austral spring and summer, but is not locally released back to the atmosphere during the winter (Bianchi et al., 2009). Assuming steady state, the net annual mean absorption of CO_2 must be balanced by net export, either to the sediments or offshore. Thus, export of shelf waters near the Subtropical Shelf Front and the Brazil/Malvinas Confluence may also be a significant regional carbon sink.

Relatively little is known about the circulation over the southwestern Atlantic shelf, and much less about its exchanges with the deep ocean. In this article we review these subjects using the latest modeling and observational results. Our discussion is focused on the influence of the neighboring western boundary currents, the Brazil and Malvinas currents, on the shelf circulation. This article is organized as follows. After this introduction, in Sect. 2, we make a brief description of the numerical simulations used in the following sections. Sections 3, 4, and 5 describe the circulation and cross-shelf exchanges in the South Brazil Bight, the Patagonian Shelf, and the region of influence of the La Plata River. Section 6 summarizes and discusses the previous results.

2 Methods

This review is mostly focused on numerical results with comparison to observations where available. The numerical simulations are described in detail in Palma et al. (2008) and Palma and Matano (2009). Our discussion focuses on three specific experiments: EXP1 is the most realistic case and corresponds with EXP1 of Palma et al. (2008). This experiment was initialized with observations and forced with tides, QuikSCAT winds, freshwater discharges and nested to a large-scale, eddy-permitting Ocean General Circulation Model. EXP2 does not include tides or winds and corresponds with EXP2 of Palma et al. (2008). EXP3 is a barotropic experiment that was forced with tides and winds but excludes the influence of the western boundary currents on the shelf. It corresponds with EXP5 in Palma et al. (2008).

Observational data comprises hydrographic sections, surface drifters (in the deep ocean), and satellite derived SST and chlorophyll-*a*. Quality controlled historical hydrographic data were used in this analysis. The hydrographic data over the continental shelf were obtained from

the Centro Argentino de Datos Oceanográficos (CEADO, <http://www.hidro.gov.ar/ceado/ceado.asp>) and Instituto Nacional de Investigación y Desarrollo Pesquero, Argentina (INIDEP, 2010), while data from the offshore region were retrieved from both, CEADO and the US National Oceanographic Data Center World Ocean Database (Boyer et al., 2009, http://www.nodc.noaa.gov/OC5/WOD09/pr_wod09.html). WOCE-Surface Velocity Program type satellite tracked surface drifters drogued at 15 m depth were used. SvP drifters are designed to follow the water to within $\pm 0.13 \text{ m s}^{-1}$ in 10 m s^{-1} winds (Niiler et al., 1995). The original position data have been quality controlled and optimally interpolated to uniform six-hour interval trajectories (Hansen and Poulain, 1996). The data are available at NOAA Atlantic Oceanographic and Meteorological Laboratory (AOML, <http://www.aoml.noaa.gov/phod/index.php>). The satellite chlorophyll-*a* data are Level 3, monthly mean Standard Mapped Images of 9 km resolution derived from the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) for the period 1998–2009, provided by NASA/Goddard Space Flight Center (see O'Reilly et al., 2000).

3 The influence of the Brazil Current on the South Brazil Bight

The South Brazil Bight (SBB) is located between Cape Frio (23° S) and Cape Santa Marta ($28^\circ 40' \text{ S}$) (Fig. 1). Its circulation is driven by low-amplitude tides, northeasterly winds, and the poleward flow of the BC along the shelf's edge. Although the region has no significant freshwater inputs, the southern portion of the bight shows intrusions of low-salinity waters from the La Plata River (Piola et al., 2000). The influence of local (e.g., winds, tides, etc) and remote forcing (e.g., the BC) on the shelf circulation has marked regional variations. The inner shelf is predominantly driven by local winds while the middle and outer shelves are more influenced by the BC (Palma and Matano, 2009). The influence of the remote forcing is most obviously manifested in the SST gradients near the shelfbreak (Campos et al., 1995; Campos et al., 2000; Castelao et al., 2004), but is not confined to the surface or to the shelfbreak. In fact, the strongest influence of the BC is observed at depth, where onshore intrusions of relatively cold and fresh South Atlantic Central Waters (SACW) extend up to the coast. These intrusions are partially related to the meandering and eddy shedding of the BC, but mostly to bottom boundary layer processes (Palma et al., 2008; Palma and Matano, 2009).

The contribution of the SACW carried by the BC to the thermohaline structure of the SBB is modulated by seasonal changes of the local wind forcing. During the summer, the SSTs over the shelf are generally higher than 23° C , except in the northwest where a tongue of colder waters associated with the onset of upwelling favorable winds generates a strong SST front near the coast (Fig. 2a). Winter SSTs,

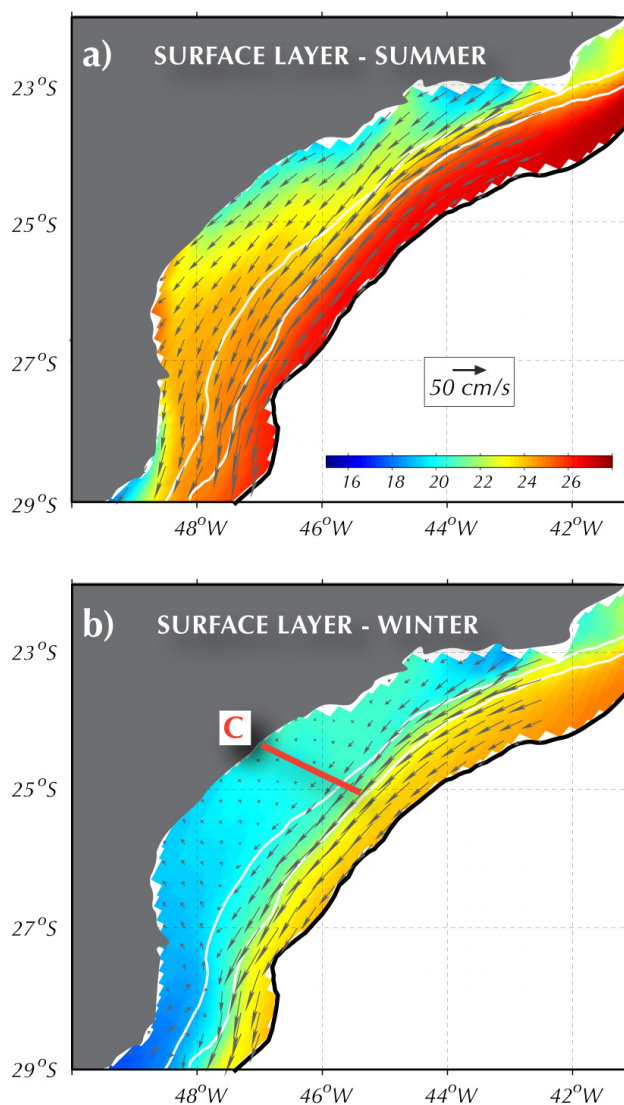

Fig. 2. Average sea surface temperatures (SSTs) and surface velocities during summer (a) and winter (b) in the numerical simulation of Palma and Matano (2009). The white line marks the position of the 100 m and 200 m isobaths. Line C marks the location of the cross-section shown in Fig. 3.

which are not influenced by coastal upwelling, are more homogeneous with values between 20° C and 23° C (Fig. 2b). The exception is the cold patch of low SSTs just south of Cape Frio, which is driven by onshore intrusions of the BC. SST gradients are larger near the shelfbreak due to the presence of the BC, and in the southern portion of the bight due to the northward advection of sub Antarctic shelf waters. The seasonal changes of the SST structure are associated with changes in the ocean circulation, particularly in the middle and inner shelf. Currents are stronger in summer, when they flow in a predominantly southwestward pattern and weaken appreciably (or even reverse) in early winter (Fig. 2b). The

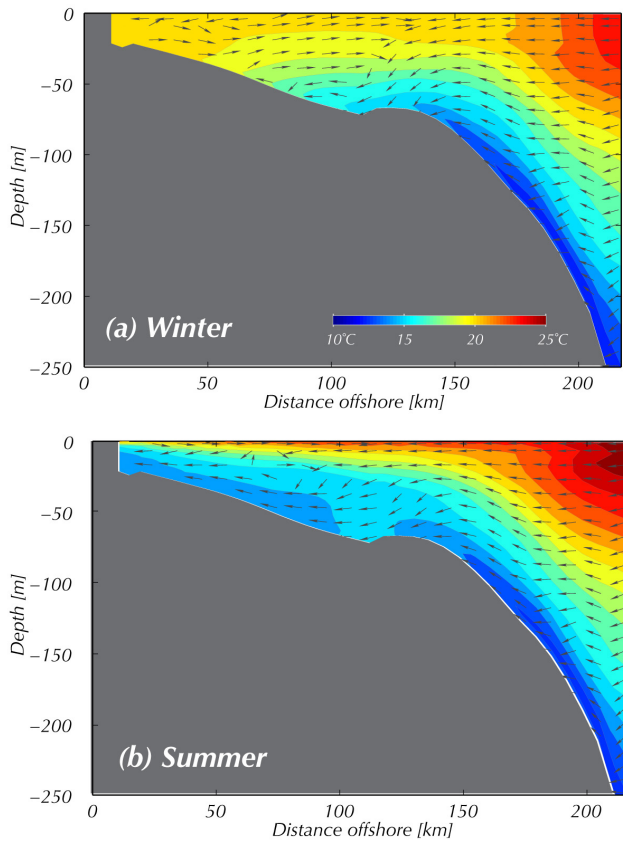

Fig. 3. Temperature and cross-shelf circulation at cross-section C from EXP1. (a) Winter, (b) Summer.

influence of the BC on the SBB is most obvious in cross-shelf sections, which show subsurface tongues of cold and saltier waters from the BC extending from the slope to the middle shelf during the winter months (Fig. 3a). During the summer, upwelling favorable winds move these waters farther inshore where they outcrop into the surface layer (Fig. 3b).

As noted above, the water mass structure of the SBB is modulated by intrusions of the BC onto the middle and outer shelf, and by wind-driven upwelling in the inner shelf. The relative importance of these mechanisms has been quantified in process-oriented experiments by comparing the previous results with an experiment without tidal and windforcing (EXP2). Thus, in this experiment the only source of momentum for the shelf circulation is the presence of the BC flowing along the continental slope. The surface circulation of EXP2 is characterized by a strong southwestward flow along the outer shelf that decreases rapidly towards the coast (Fig. 4a). The summer SST field over the shelf in this experiment is nearly uniform, showing the influence of wind forcing on the observed SST structure. The contribution of the local winds to the shelf circulation is also clearly appreciated in the velocity field, which shows an almost stagnant inner shelf in EXP2 (Fig. 4a). The onshore intrusions of the BC

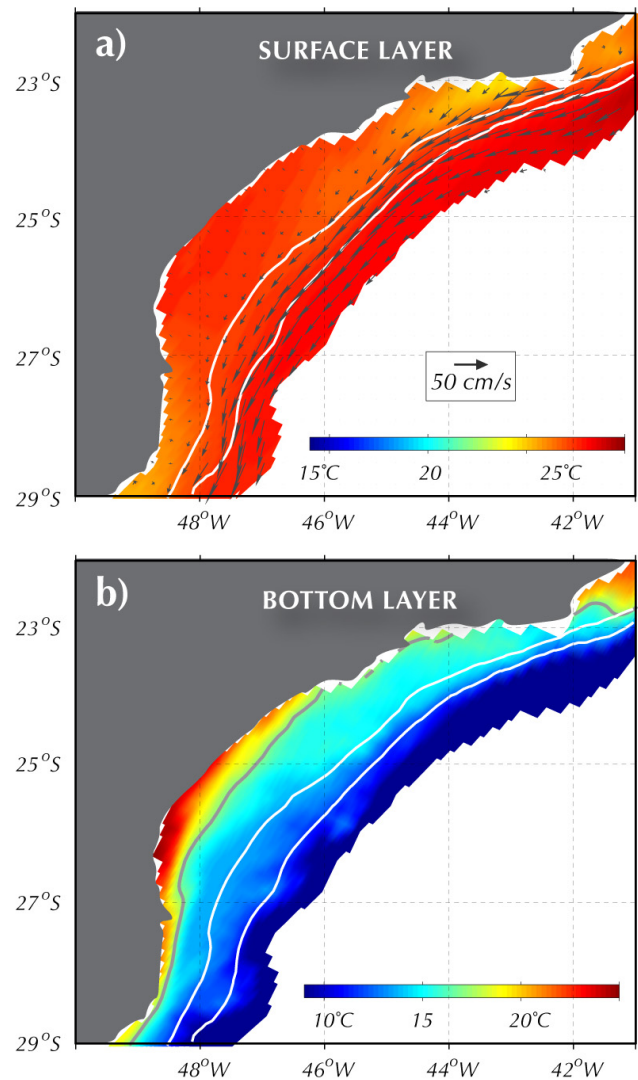

Fig. 4. EXP2: (a) Summer sea surface temperature and surface velocity vectors and (b) Bottom temperature. White contours mark the 100 and 200 isobaths. The black line in panel (b) is the 17 °C isotherm, indicative of the SACW penetration. Note that each panel uses a different color bar.

in the bottom boundary layer are appreciated in the location of the 17 °C isotherm, which is representative of SACW, and which moves closer to the coast during the summer months (Fig. 4b). As noted above, upwelling favorable winds (in EXP1) further draw these waters toward the coast and force their outcrop to the surface (Fig. 3b).

To further quantify the influence of the BC on the shelf circulation we calculated the alongshelf momentum balances in the bottom boundary layer (Fig. 5). There is little difference between the curves representing the Coriolis term ($f.U$) in the middle and outer shelf but there are important differences in the inner shelf. This indicates that the cross-shelf velocities of the outer and middle shelf are largely driven by the

Fig. 5. Alongshelf component of the momentum balance across section C during summer.

barotropic pressure gradient associated with the Brazil Current, while direct wind forcing significantly influences the cross-shelf velocities in the inner-shelf. Further analysis by Palma and Matano (2009) shows that changes in the coastline orientation modify the spatial patterns of cross-shelf exchanges. In particular the latitudinal change of the shelf width reverses the direction of the alongshelf pressure gradient and augments the onshore flow towards the north.

In summary, our experiments indicate that the water mass structure and circulation of the SBB is controlled by the synergetic interaction between wind-driven upwelling in the inner shelf and onshore intrusions of the BC in the middle and outer shelf. The wind effect peaks during the austral summer and decreases towards the winter while the influence of the BC shows no significant seasonal variation. As shown in previous work the circulation patterns and density structures derived from the numerical simulations correspond well with observations (Campos et al., 1995; Palma and Matano, 2009). The interaction between the poleward flow of the BC and the bottom topography greatly influences the nearshore circulation, particularly in the bottom boundary layer. Changes of the width of the SBB modulate the alongshore pressure gradient and the magnitude of the shelf-break upwelling and downwelling. Thus, although the summer upwelling winds extend over the entire region the SSTs are warmer in the south because of the cooling effect of the shelfbreak upwelling in the northern region. As noted by Palma and Matano (2009), the narrowing of the shelf in the southern portion of the bight leads to an enhancement of the vertical mixing in some situations (e.g., when there is an increase in the BC transport or the magnitude of the windstress forcing) and can overcome the unfavourable alongshore pressure gradient and promote upwelling.

4 The influence of the MC on the Patagonian shelf

The Patagonian shelf extends from the tip of South America (~55° S) to the Brazil/Malvinas Confluence (~38° S) (Fig. 1). This vast coastal region is subject to the combined effects of strong westerly winds, high amplitude tides, large low-salinity discharges, and the neighboring presence of the MC. Its mean circulation is characterized by a broad north-eastward flow that intensifies towards the shelfbreak, where it merges with the MC (Figs. 1 and 6). South of ~49° S there is a well-defined jet in the inner shelf, known as the Patagonian Current, that is generated through the interaction of tidal currents and the Magellan Straits discharge (Palma et al., 2008) (Fig. 1). The vertical structure of the shelf circulation is roughly equivalent to a two-layer system, with the flow in the upper layer directed towards the northeast and in the bottom layer towards the southwest (Fig. 7a and c). A simple mass balance shows that the northward outflow of surface waters is compensated by inflow at deeper levels. The largest entrainment of deep waters is observed through the

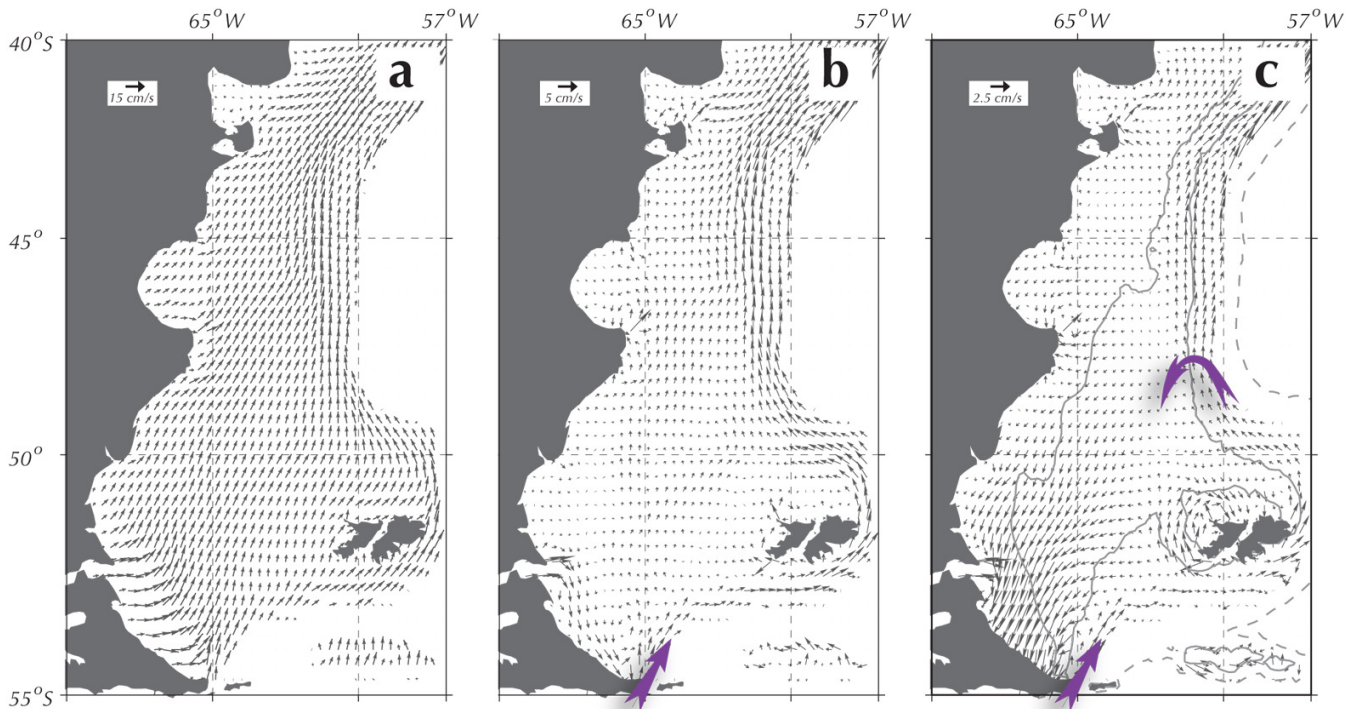

Fig. 7. Time averaged velocities at the upper, intermediate, and bottom levels of EXP1. The purple arrows mark the regions of largest cross-shelf exchanges.

Le Maire Straits (at the tip of Tierra del Fuego) and to the north of the Malvinas Islands (Fig. 7b, c). Similar intrusions have been reported in observations e.g., Sabatini et al. (2004, their Fig. 8) and Romero et al. (2006, their Fig. 8). As these waters move onshore they generate coastal upwelling along the southern portion of Patagonia. This coastal upwelling, however, is relatively weak and it is not easily visualized in the SST fields due to intense tidal mixing (Rivas and Pisoni, 2010).

One of the most distinct characteristics of the Patagonian region is the narrow and persistent chlorophyll maximum that closely follows the 200 m isobath (Romero et al., 2006) (Fig. 8). The peaks of this maximum are unusually high. Spring blooms, for example, have surface values of 25–30 mg/m³, which are an order of magnitude larger than those observed in typical offshore locations (e.g., Acha et al., 2004; Romero et al., 2006; Garcia et al., 2008; Signorini et al., 2009). The chlorophyll blooms of the MC are symptomatic of the upwelling of nutrient-rich waters to the surface, but the mechanisms driving such upwelling are still poorly understood. External forcing does not appear to be the cause: the winds in the Patagonia region are not upwelling-favorable, tidal mixing is relatively small in the shelfbreak region and, as noted above, the MC does not show the eddy shedding and meandering that drive the upwelling of other western boundary systems (e.g., the Gulf Stream). It has been recently postulated that the shelfbreak upwelling of Patagonia is associated with frictionally driven intrusions of the

MC onto the shelf (Matano and Palma, 2008). These intrusions generate an alongshelf pressure gradient with a secondary cross-shelf divergence cell that leads to shelfbreak upwelling. The magnitude of the upwelling is proportional to the transport of the MC and to the ratio of the bottom slopes at both sides of the shelfbreak (Matano and Palma, 2008). The upwelling of Patagonia is qualitatively and quantitatively different than that proposed for the shelfbreak of the Middle Atlantic Bight, its northern hemisphere counterpart, because of the fact that the former lacks the equivalent of the Labrador Current while the latter lacks the equivalent of the MC. Modeling studies indicate that the upwelling velocities along Patagonia's shelfbreak are of the same order of magnitude as those in typical wind-driven upwelling systems (Matano and Palma 2008). The difference is that, while most wind-driven events last only a few days or weeks, the upwelling of Patagonia can be continuously sustained throughout the entire year. There are coastal regions with year-round upwelling favorable winds (e.g., the western coast of Africa) but, unlike Patagonia, they are not embedded within the nutrient rich waters of the Southern Ocean and their influence is restricted to the nearshore region. The impact of Patagonia's shelfbreak upwelling on the regional ecosystems appears to extend well beyond the shelfbreak region. Chlorophyll-a images, for example, indicate that the subpolar portion of the South Atlantic is the most productive portion of the entire Southern Ocean while the subtropical open-ocean region is a relative desert (<0.2 mg/m³, Fig. 8).

Fig. 8. SeaWiFS derived surface chlorophyll distribution averaged between 17–24 January 2009 in the southwestern Atlantic region.

The influence of the MC on the coastal circulation is more easily appreciated by comparing the results of EXP1 with a barotropic experiment that excludes the MC (Fig. 9). The remarkable differences between these experiments shows that the influence of the MC extends from the outer to the inner shelf. The cross-shelf component of the vertically averaged momentum balance, for example, indicates a 2- to 4-fold increase of the alongshelf transport. This increase reflects the influence of the barotropic pressure gradient associated with the MC and is particularly noticeable in the middle shelf. Note that in EXP3 there is no net alongshelf transport and, therefore, the northward wind-driven transport in the surface Ekman layer is compensated by a similar southward transport in the bottom boundary layer. In EXP1, however, there is a substantial net alongshelf transport whose spatial variations reflect the mass exchanges between the shelf and the deep ocean that are generated by the MC.

The Patagonian shelf exports surface waters to the deep ocean and imports deeper waters through the Le Maire Straits and the shelfbreak region (Fig. 7). Shelfbreak upwelling draws cold and denser waters to the surface whence they move onshore and downward. After reaching the middle and inner shelf these waters are uplifted towards the surface by

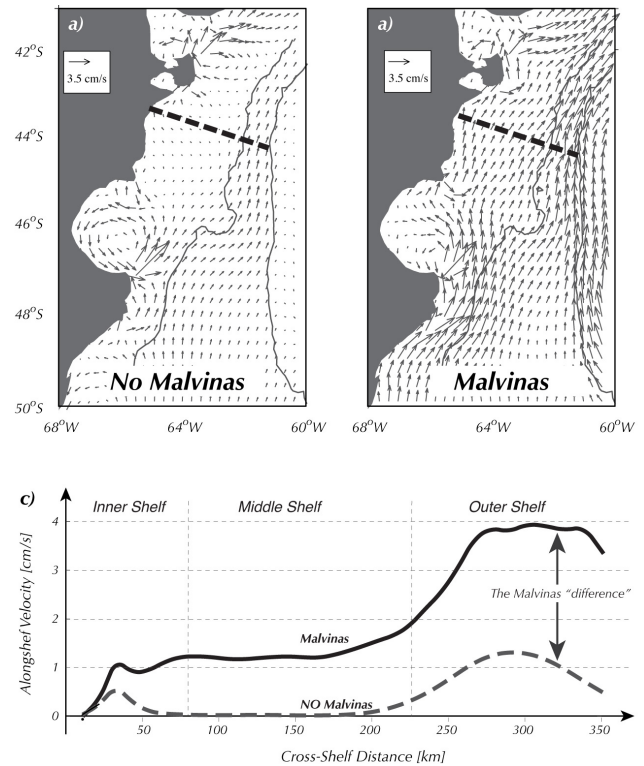

Fig. 9. (a) Depth averaged velocities in EXP2; (b) EXP1; (c) Alongshelf velocities across the section shown in the upper panels. The differences between these two experiments are mainly due to the MC.

strong tidal mixing and are diverted to the north in the surface Ekman layer (Fig. 10). The nutrients carried by these waters add to the nutrient flux produced by re-suspension and cause additional chlorophyll blooms along the inner- and middle-shelf of Patagonia (Fig. 8). These cross-shelf exchange patterns are consistent with observations. A cross-shelf hydrographic section across 51° S, for example, typifies the water mass structure and circulation of this region (Fig. 11a). The density profile shows a typically weak pycnocline and a small wedge of low-density waters very close to the shore. This coastal minimum is associated with the presence of fresher waters from the Magellan Strait. Farther offshore there is a second density front at approximately 300 km from the coast. This front marks the boundary between the coastal and shelf water masses. The advection of sub Antarctic waters by the MC is evident over the outer continental shelf where there are sharp gradients of temperature and salinity in the deep layers. The isopycnals show three retrograde fronts, which have been associated with the development of baroclinic cells of circulation (Fig. 11b). Thus, model and observations suggest a cross-shelf circulation pattern dominated by upwelling and onshore intrusions of cold and dense Malvinas water in the outer shelf. After moving away from the shelfbreak these waters sink and are drawn to the inner shelf where they are lifted

Fig. 10. Schematic representation of the cross-shelf exchanges in the Patagonia shelf region. Sub Antarctic waters upwelled along Patagonia's shelfbreak move onshelf and sink. Near the coast these waters are drawn upward by tidal mixing, and after reaching the surface they are advected to the north by the westerly winds. A portion of these waters is likely to be diverted offshore in the surface Ekman layer while the remainder might reach the Brazil/Malvinas Confluence and the STSF where they are likely to be detrained by the mean circulation.

again by tidal forcing. As these waters reach the mixed layer they are diverted to the north by the westerly winds (Fig. 10). The inshore flux through the Patagonia shelf is compensated by offshore fluxes at the Brazil/Malvinas Confluence and at the STSF.

In a recent study Piola et al. (2010) also showed intrusions of the MC onto the northern Patagonian shelf near 41° S. These intrusions, which extend throughout the entire water column, generate low temperature and high salinity anomalies that extend through the midshelf region. These onshore intrusions of the MC are also associated with distinct chlorophyll peaks, such as the one observed in spring 2003 (Piola et al., 2010; Signorini et al., 2009). The mechanisms generating these intrusions are still poorly understood although it appears to be due to topographic steering of the MC; the inshore turn of isobaths within the 90–110 m depth range might drive inshore waters from the western edge of the MC.

5 The Subtropical Shelf Front (STSF)

Located near 33° S, the STSF separates the warm and salty waters of the SBB from the cold and relatively fresh waters of the Patagonian Shelf (Fig. 12a). The STSF extends from the near surface, where it is capped by low salinity waters drawn from the La Plata River and the Patos/Mirim complex, to the bottom (Fig. 12b). Although the front appears as a shelf extension of the Brazil/Malvinas Confluence, the contribution of the western boundary currents to its formation remains unclear. Piola et al. (2000, 2008) observed that while the Brazilian sector of the shelf shows inshore intrusions of the Brazil Current (manifested as SACW in their T-S diagrams), the waters in the Argentinean sector are substantially fresher

Fig. 11. Density cross-shelf section off Grande Bay ($\sim 51^{\circ}$ S) from a hydrographic cruise in March 1994 (top panel). Schematic showing the fronts identified in this section and the inferred circulation patterns. (After Sabatini et al., 2004).

than those carried by the Malvinas Current. Thus, while there is evidence that the BC moves over the shelf, and therefore might influence the frontal structure, there is no evidence of similar behavior by the Malvinas Current. The cross-shelf sections analyzed by Piola et al. (2008) also indicate that there is neither northward penetration of sub-Antarctic shelf waters to the north of the front nor southward penetration of the subtropical shelf waters to the south. Both water masses, therefore, should be advected offshore at this location.

As noted above, it remains unknown what are the dynamical mechanisms that lead to the formation and determine the location of the STSF. Like the Cape Hatteras Front, its northern hemisphere counterpart (Stefansson et al., 1971; Pietrafesa et al., 1994; Savidge, 2002), the STSF appears to be an onshore extension of the barotropic pressure gradients associated with the neighboring western boundary currents. This hypothesis is reinforced by observations showing that the front is essentially barotropic, i.e., that it has a density compensated thermohaline structure. Thus, there is a distinct front in temperature and salinity but not in density (Piola et al., 2000). Although observations show direct intrusions of waters of the BC onto the shelf, but not from the MC, numerical experiments indicate that the MC still plays an important role in the front location through its barotropic pressure gradient (Palma et al., 2008). The STSF appears to be a preferential region for the detrainment of the cross-shelf inflows from the BC and MC (Fig. 13). Thus, waters entrained throughout the shelfbreaks of the SBB and Patagonia are ejected offshore in this region. The bio-geochemical properties of these water masses are enhanced by the freshwater discharges from the La Plata River and the Patos/Mirim Lagoon, making the STSF a critical component of the cross-shelf exchanges in the Southwestern Atlantic.

Fig. 13. Snapshot of SST and velocities in EXP1. This figure shows a classic configuration of the circulation in this region, which is characterized by the detrainment of shelf waters onto the deep ocean.

6 Summary and discussion

In this article we reviewed the influence of the BC and MC on the circulation of the southwestern Atlantic shelf. The influence of the BC is most visible through sporadic onshore intrusions of eddies and meanders, but it has been argued that this is not the only – nor its most important – contribution to the shelf dynamics. In fact, numerical simulations show that the thermohaline structure of the SBB can be entirely ascribed to steady state, bottom boundary layer processes. The determination of the cross-shelf exchanges over Patagonia is much simplified by the weak density stratification of the region, which basically locks the path of the MC to the bottom topography inhibiting the development of mean flow instabilities. Drifter trajectories in this region, for example, do not show the convoluted loops that characterize the path of unstable currents, but extend from the Drake Passage to the Brazil/Malvinas Confluence in remarkably smooth tracks (Fig. 14). This characteristic of the MC allows the use of a well-developed body of theoretical models to identify the region most favorable for cross-shelf exchanges. For example, the arrested topographic wave theory of Csanady (1978) predicts that the onshore penetrations of the MC onto the shelf should be inversely proportional to the steepness of the continental slope. Regions of steep slope, therefore, should allow a smaller penetration than regions with gentler slopes. Based on these arguments, Hill (1995) argued that if the transition between two regions occurs in a distance smaller than that required by the geostrophic adjustment ($L \sim fh_x b^2/r$, where h_x is the bottom slope, b is the width of the western boundary current, and r is the bottom friction coefficient), ageostrophic effects should generate substantial cross-shelf flows to account for the disparity in the bottom slopes. There is a well-defined transition in the steepness of the continental slope between $\sim 50^\circ$ S and 48° S (Fig. 15). This transition occurs in a distance of less than 300 km, which is much smaller than the

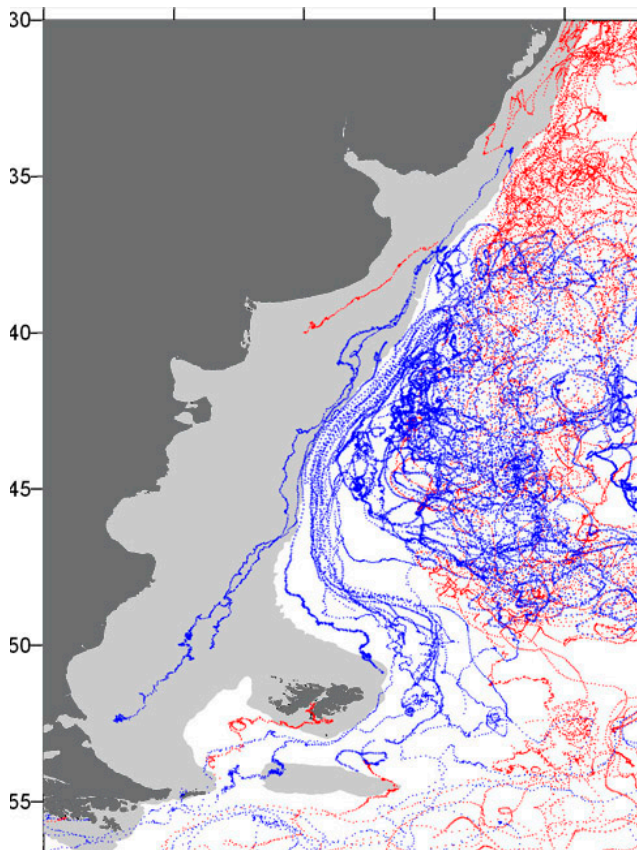

Fig. 14. Trajectories of satellite tracked “surface” drifters from WOCE-Surface Velocity Program type. The drifters are drogued to 15 m depth and designed to follow the water to within $\pm 0.13 \text{ m s}^{-1}$ in 10 m s^{-1} winds (Niiler et al., 1995). The original position data have been quality controlled and optimally interpolated to uniform six-hour interval trajectories (Hansen and Poulain, 1996). Note the quasi-linear trajectories of the drifters in the MC.

scale required by geostrophic adjustment, i.e., $L \sim 2000 \text{ km}$ (considering a $f=2 \times 10^{-4} \text{ s}^{-1}$, $r = 10^{-3} \text{ m s}^{-1}$, $b = 100 \text{ km}$, and $h_x=1 \times 10^{-3}$). Hill’s hypothesis is in good agreement with the results of the numerical simulation (e.g., Fig. 7c). The arrested topographic wave theory, however, is strictly valid for a barotropic fluid and although the MC is very weakly stratified it still needs to be determined whether the downstream topographic scale is indeed much smaller than the geostrophic adjustment scale for the MC. It seems likely that the strong entrainment observed in the region to the north of the Malvinas Islands is partly explained by Hill’s hypothesis and partly by non-linear ageostrophic effects associated with the narrowing of the MC and the curvature of its path, i.e., confronted with a sudden turn of the bottom topography inertia can force a portion of the MC to “spill over” the shelf.

The inflow through the Le Maire Strait is not restricted to the bottom boundary layer but extends throughout the entire water column, thus suggesting a different entrainment

Fig. 15. Bottom topography of the Patagonian shelf. Note the rapid convergence of the isobaths north of $\sim 50^\circ \text{ S}$.

mechanism (Fig. 7). We surmise that cross-shelf fluxes in this region are driven partly by inertial fluxes across bending isobaths, and partly by the interaction of the M_2 tide with the bottom topography. Similar processes have been identified in George’s Bank where it was observed that enhanced vertical mixing and horizontal gradients lead to secondary circulation cells that account for most of cross-shelf fluxes (Franks and Chen, 1996). In these regards it should be noted that southern Patagonia has one of the largest M_2 tide amplitude range of the world ocean. Tides are unlikely to play an equally important role in the northern region because the M_2 tide enters Patagonia through its southern boundary and travels as a Kelvin wave with its maximum amplitude largely confined to the inner shelf (Palma et al., 2004). Wind stress forcing is another important promoter of cross-shelf exchanges. Pringle (2002) postulated that alongshelf variations of the shelf width should generate cross-shelf fluxes that compensate for changes of the wind-driven Ekman transports. According to this theory the observed narrowing of the Patagonia shelf in the region between $\sim 50^\circ \text{ S}$ and 48° S , should favor an outflow of shelf waters onto the deep ocean. However, as noted in our previous discussion, this region is also characterized by an abrupt change of the continental slope that should intensify the intrusion of the MC onto the shelf. The cross-shelf fluxes associated with the MC and the shelf circulation, therefore, oppose each other and, in principle, should lead to a further strengthening of the alongshelf circulation north of $\sim 48^\circ \text{ S}$. Interestingly this strengthening can be inferred from observations and it is a ubiquitous feature of our previous numerical simulations (e.g., Fig. 7).

7 Perspectives

Although our understanding of the exchanges between the deep ocean and the southwestern Atlantic shelf is very limited it is obvious that their nature and magnitude vary dramatically from north to south. So do the questions concerning each of its distinct regions. A central question concerning the exchanges in the South Brazil Bight is whether they are controlled by eddy fluxes or by steady intrusions from the bottom boundary layer. This is a difficult question because transient and mean flows are naturally concatenated, but it is important because it concerns properties of the exchanges such as nutrient content, residence time, etc. It is difficult to address this question using observations. Satellite measurements, for example, display eddy-like features along the onshore edge of the Brazil Current, but these data are only representative of the ocean surface. Hydrographic and current meter observations are scarce, and, due to the extent of the region, acquisition of new data is logistically difficult and expensive. New numerical simulations, however, can help the design of observational programs. For example, realistic models can be used to assess the location of the main cross-shelf exchanges, while process-oriented simulations can help to elucidate the dynamical processes responsible for those exchanges. Considering that one of the crucial problems of comparing actual simulations is their dissimilarities, i.e., spatial and temporal domain, mixing parameterization, spatial resolution, etc., it seems particularly important to encourage model developments that allow the assessment of the robustness of the results. One of the portions of the South Brazil Bight that seems more interesting for focused numerical and observational studies is the Cape Frio region, where the curvature of the coastline and the narrowness of the shelf synergize the interaction between local and remotely forced phenomena.

Patagonia is one of the most interesting portions of the southwestern Atlantic shelf, not only because of its high primary production, but also because it is the main conduit for terrigenous fluxes into the Southern Ocean. Thus, determining the magnitude and nature of its cross-shelf fluxes is relevant to our understanding of the entire Southern Ocean ecological system. Fortunately, these exchanges appear to be more amenable to modeling and observational studies than other shelf regions, partly due to the weak density stratification in the outer shelf and partly to the remarkable stability of the Malvinas Current. A central question is whether these cross-shelf fluxes are modulated by the bottom topography and variations in the transport of the MC. These questions have been addressed in highly idealized models e.g., Hill (1995), Matano and Palma (2008) but it remains to be seen whether the same results are apparent in more realistic simulations.

Present simulations suggest that most of the waters entrained in the SBB and the Patagonia shelf are detrained near the Brazil/Malvinas Confluence and the Subtropical Shelf

Front. The circulation in this middle region, therefore, appears to be key component of the processes connecting the southwestern Atlantic shelf to the deep ocean.
